ARTICLE INFO

ABSTRACT

Inspired by a growing body of empirical work, this paper models a non-linear labor income process allowing for a personal disaster, such as long-term unemployment or disability, during working years. Such a disaster entails an uncertain but potentially large permanent shock to earnings. Personal disaster risk allows to match moderate risk-taking of young investors and a flat investment profile in age, observed in the United States, when the calibration of both the disaster probability and the expected permanent loss in the disaster state is conservative.

1. Introduction

What happens if a person's future ability to work is permanently reduced? Insurance against permanent shocks, such as disability and long-term unemployment, is well known to be incomplete (Guvenen & Smith, 2014; Low & Pistaferri, 2015; Meghir & Pistaferri, 2004). Therefore, young households make provisions to cushion against a personal disaster, even if the possibility of its occurrence is quite rare. Against this background, the current paper examines the pattern of self-insurance in financial markets over the life-cycle when there is the possibility of a rare personal disaster during working years.

The findings show that personal disaster risk can alter lifetime *ex-ante* investment choices for the average worker, even if *ex-post* most workers will not experience a disaster. Additionally, this paper reveals that uncertainty about the size of uninsured human capital losses, which characterizes rare disasters, enhances the precautionary behavior of young workers. This behavior will result in lower risk-taking at the beginning of working life, with respect to a comparable deterministic human capital loss. Uncertainty about the extent of losses is crucial in order to closely match the observed age profiles of US investors from 1992 to 2016, based on the methods of Ameriks and Zeldes (2004), when the calibrations are conservative.

We contribute to the household finance literature by linking risk-taking in financial markets to the *ex-ante* uncertain, but potentially extreme, permanent impact of income shocks. In contrast to this literature, however, we go beyond the positive probability of zero labor income implied by the linear income process proposed by Cocco, Gomes, and Maenhout (2005) and later widely adopted in the field. Inspired by a growing body of empirical work showing that earnings dynamics display non-linearities

(Arellano, Blundell, & Bonhomme, 2017; Catherine, 2022; De Nardi, Fella, & Paz-Pardo, 2020; Galvez & Paz-Pardo, 2023; Guvenen, Karahan, Ozkan, & Song, 2021; Inkmann, 2020; Karahan & Ozkan, 2013; Sanchez & Wellschmied, 2020; Shen, 2023), we model the occurrence of a disaster that brings about a permanent income reduction of uncertain proportion.

Specifically, the fraction of human capital lost follows a *Beta* distribution.[1] The flexibility of such distribution allows us to concentrate a large probability mass on small values of proportional human capital reduction while leaving open the possibility of extremely unlikely but devastating realizations. This feature of the model is intended to capture the substantial heterogeneity of permanent effects following the occurrence of adverse occupational and/or health shocks documented by Gregory, Menzio, and Wiczer (2021) and Guvenen et al. (2021).

Importantly, when careers are calibrated to broadly match observed US labor market features, optimal investment in the risky asset remains flat over the whole working life, in line with early evidence on US portfolios (Ameriks & Zeldes, 2004), which we update to 2016. This situation occurs even when we account for the large insurance coverage of permanent income shocks, as in Guvenen and Smith (2014) and Guvenen et al. (2021), which may ultimately reduce the expected human capital losses due to long-term unemployment. Without disaster risk, the implied optimal stock holding still counter-factually decreases with age before retirement, unless the long-term unemployment rate is as high as that observed in the post-Great Recession and protracted inactivity causes a certain and relatively large human capital drop for all long-term unemployed, as in Bagliano, Fugazza, and Nicodano (2019).

With respect to the latter paper, we calibrate long-term unemployment risk in a more realistic fashion, and model permanent earnings losses due to long unemployment spells as stochastic, rather than deterministic. This new setting allows to see clearly the true driving force of the flat risky investment age profile: it is not the mere prospect of a permanent human capital loss, but the possibility that, though only in extremely rare cases, that loss amounts to a substantial fraction of future permanent earnings (the "rare disaster" scenario), an occurrence which is absent in the existing literature.

Our results highlight the role of non-linear income shocks in flattening the age profile of risk taking. With a linear income process, prior models resort to using additional features to explain reduced risk-taking in financial markets (Bagliano, Fugazza, & Nicodano, 2014; Branger, Larsen, & Munk, 2019; Chang, Hong, & Karabarbounis, 2018; Cocco, 2004; Hubener, Maurer, & Mitchell, 2016; Kraft & Munk, 2011; Munk & Sorensen, 2010). For instance, in Bagliano et al. (2014), a positive correlation between (highly volatile) permanent income shocks and stock returns leads to lower optimal risk-taking when young. Branger et al. (2019) obtain reduced early-life holdings by setting the probability of losing a job and experiencing a subsequent human capital loss as decreasing in the worker's age and in the state of the economy. Finally, in Chang et al. (2018) the driver of low risk-taking when young is related to uncertainty which resolves over time thanks to agents' learning about their income volatility. The resolution of uncertainty due to this learning process explains why the young bear more labor income risk, an intuition pioneered by Benzoni, Collin-Dufresne, and Goldstein (2007) and Viceira (2001).

In our paper, uncertainty resolves because time passes without the occurrence of disasters. More precisely, we model working life careers as a three-state Markov chain driving the transitions between employment, short-term unemployment and personal disaster states. Uncertain permanent earning losses that occur in the disaster state, represent productivity loss due to long-term unemployment (Arulampalam, 2001; Schmieder, von Wachter, & Bender, 2016), disability or both (Low & Pistaferri, 2015).

This model nests the traditional life-cycle framework within the household finance literature. Indeed, when the disaster probability is zero and/or human capital erosion is compensated by full insurance, the agents optimally reduce exposure to risky assets as they approach retirement. This pattern obtains since human capital provides a hedge against shocks to stock returns, which makes bearing financial risk generally acceptable. Investment in stocks should therefore be relatively high at the beginning of working careers, when human capital is large relative to accumulated financial wealth. Risky investment then gradually declines until retirement, as human capital decreases relative to financial wealth.

When personal disaster risk is instead only partially insured, the above effect is moderated by the resolution of uncertainty concerning labor and pension income as the worker safely approaches retirement age.[2] Since the risk of a personal disaster declines as an individual approaches retirement, the resolution of uncertainty compensates for the hedge effect and the optimal investment in stocks is relatively flat over the life cycle.

Our model delivers additional implications concerning life-cycle choices in the context of incomplete insurance against personal disaster risk. First, the distribution of optimal consumption growth becomes negatively skewed, due to disasters, in line with evidence on durable consumption growth (Yang, 2011). Second, personal disaster risk changes the age profile of savings thereby shrinking the heterogeneity of optimal portfolio choices across agents characterized by different career histories. Young workers increase early precautionary savings to buffer against possible, albeit rare, future disasters. Optimal consumption consequently declines during the early years but increases during both late working years and retirement. Third, the average implied savings to income ratio increases, as in other life-cycle models highlighting the role of earnings shocks for solving life-cycle portfolio choice puzzles (Bagliano et al., 2014; Chang et al., 2018). While the implied savings to income ratio may appear counter-factually high, our model does not incorporate the effects of means-tested welfare programs that lead to zero optimal precautionary saving for poor households (Hubbard, Skinner, & Zeldes, 1995).

This model does not address non-participation in the stock market. It should otherwise allow for correlation between stock returns and labor income shocks (see Bagliano et al. (2014) for additional conditions and Bonaparte, Korniotis, and Kumar (2014)

---

[1] This distribution may also characterize the damage caused by natural disasters (see Bhattacharjee, 2004; Lallemant & Kiremidjian, 2015).

[2] We do not model the option to change labor supply to buffer income shocks, as in Bodie, Merton, and Samuelson (1992) and Gomes, Kotlikoff, and Viceira (2008). This option is open to those who find a new job, while what drives our results is the *ex ante* possibility of a large loss in the disaster state.

Table 1
Descriptive statistics: SCF data 1992–2016.

The table reports the average composition of households financial assets and demographic characteristics across various SCF waves (1992–2016). The sample is restricted to households with heads aged between 21 and 70 years and with a positive amount of financial assets.

for empirical results) or correlation between stock returns and the skewness of labor income shocks (Catherine, Sodini, & Zhang, 2020). Likewise, prominent papers study consumption and labor market choices with permanent income shocks (Low & Pistaferri, 2015; Meghir & Pistaferri, 2004), focusing on the design of social insurance against employment and productivity risk without allowing for investments in risky assets.

Our paper belongs to the household finance tradition that allows for risky investments but overlooks both moral hazard stemming from social insurance programs and the associated difference between productivity and employment risk. Finally, the personal disaster risk modeled in this paper differs from both the individual stock market disaster in Fagereng, Gottlieb, and Guiso (2017) and the aggregate economic collapse in the macro-finance literature (Barro, 2006), although disasters may be correlated. As Arellano et al. (2017) point out, macroeconomic disasters are statistically elusive events, while disasters at the micro level happen all the time.

The rest of the paper is organized as follows. In Section 2 we provide evidence on life-cycle portfolio holdings and institutional details on long-term unemployment, disability and social insurance for the United States. Section 3 presents the benchmark life-cycle model and briefly outlines the numerical solution procedure adopted. We detail the model calibration in Section 4 and discuss our main results in Section 5, where the ability of the model to match the stock-holdings observed in real data is also assessed. Section 6 concludes the paper. A Supplementary Appendix provides additional robustness results.

2. Households portfolios and personal disasters

This section presents the main stylized facts concerning financial risk-taking and personal disaster risk in the United States. The first subsection builds on the method of Ameriks and Zeldes (2004) to examine the empirical relationship between age and conditional risky shares, i.e. the fraction of financial wealth held in risky assets conditional on participation in the stock market. These life-cycle investment profiles in US data will later be matched with the model-implied profiles. Since such profiles are calibrated to disaster risk, the second subsection summarizes some relevant features of disability and long-term unemployment.

2.1. Life-cycle profiles of households portfolios

We pool data from the independent cross-sectional surveys in the Survey of Consumer Finances (SCF), covering the years from 1992 to 2016. The SCF is nationally representative of households in the United States and collects detailed information on their characteristics and investment decisions. Following Chang et al. (2018), we classify the households' financial assets into two categories, *safe* and *risky*. Safe assets include: checking accounts, savings accounts, money market accounts, certificates of deposit, the cash value of life insurance, US government and state bonds, mutual funds invested in tax-free bonds and government-backed bonds, and trusts and annuities invested in bonds and money market accounts. Risky assets include: stocks, stock brokerage accounts, mortgage-backed bonds, foreign and corporate bonds, mutual funds invested in stocks, trusts and annuities invested in stocks or real estate, and pension plans that are thrift, profit-sharing, or stock purchase plans. In Table 1, we report the summary statistics concerning both the households' financial assets composition and their main characteristics. We restrict the sample to households with positive financial assets and with a head of household aged between 21 and 70.

Fig. 1 shows the life-cycle age profile of the average conditional portfolio share invested in risky assets, displaying five-year averages from age group 21–25 to age group 66–70. The conditional risky share is fairly flat over the life cycle, ranging from 40% to 49%.
Fig. 1. Conditional risky share - SCF data.
This figure displays the life cycle profile of conditional risky share of financial assets held by U.S. households grouped by five-year age classes (21–25, ..., 66–70).

Ideally, we should distinguish the impact of age on household risk taking from that of both calendar years and birth cohorts. However, the three effects cannot be separately identified. We therefore estimate three regression models in which we hold constant one effect at a time against the other two, following Ameriks and Zeldes (2004). The age dummies are constructed on the basis of five-year age groups, from 21 to 70, the reference group being aged between 46 and 50. Similarly, the birth year cohort dummies refer to five birth-year groups (from 1924–1928 to 1989–1993), with the cohort 1953–1958 being the reference group. Finally, the time effects refer to the years in which the surveys are collected, and 2004 represents the reference year. In Panel (a) of Fig. 2, we report the OLS regression estimates of time and age effects with cohort effects excluded (dashed and solid lines, respectively); Panel (b) displays the estimated time and cohort effects with age effects excluded (dashed and solid lines, respectively); finally, Panel (c) plots the estimated age and cohort effects with time effects excluded (dashed and solid lines, respectively).[3] The conditional risky share is remarkably flat across ages and cohorts in all specifications, with time effects showing an increase during the 1990s and a relative slowdown after year 2000. Overall, our results confirm, and extend through 2016, the patterns originally unveiled by Ameriks and Zeldes (2004).[4]

2.2. Uninsured personal disasters

This section provides an assessment of human capital losses caused by personal disasters, such as layoffs or disability. It also sheds light on estimates of the fraction of permanent income shocks that remains uninsured, touching upon heterogeneity across households and over the sample years. In Section 4 we will calibrate the labor income process and the insurance parameters of the life-cycle model against this background.

Unemployment may lead to persistent earnings losses that increase with the duration of unemployment spells, because of skill deterioration and diminishing chances of finding a new occupation. In the United States the share of unemployed workers who were jobless for more than one year, while historically low, doubled during the Great Recession, reaching 24% of total unemployment in 2014 and hitting all education groups (Kroft, Lange, Notowidigdo, & Katz, 2016).[5] The chances of finding a job decrease, together with unemployment benefits, as the duration of unemployment increases.[6]

Early estimates of persistent earnings losses due to long-term unemployment (Jacobson, LaLonde, & Sullivan, 1993a) are around 25% of average earnings six years after separation, relative to workers with similar characteristics that stayed with the same employer during the same episode. Guvenen, Karahan, Ozkan, and Song (2017) measure the effects of a full-year non-employment across workers with heterogeneous histories in a more recent sample (1978–2010). Earnings losses are in the 35%–40% range after 10 years, due to both lower chances of future employment and lower income in case of re-employment. Gregory et al. (2021), using the Longitudinal Employer-Household Dynamics dataset from 1997 to 2014, find that after 5 years, around half of displaced workers still suffers from an earnings loss between 25% and 50% of pre-displacement income. Given our focus on equity investment, it is important to stress that earnings losses are large not only for workers with low earnings but also for those in the top 5% of the past earnings distribution.[7]

Large negative shocks associated with health are another important form of personal disasters. Mental health problems have an especially large impact on labor market outcomes, possibly because they also affect prime-age workers. The onset of mental illness

---

[3] We set to zero all the coefficients that are not statistically significant from zero at the 5% level.

[4] Such patterns are also robust across education levels (results unreported here).

[5] For instance, in 2013, the share of US unemployed workers with a high school (college) education who had been looking for work for two or more years was 12.8% (13.5%) (Mayer, 2014).

[6] Kroft et al. (2016) and Krueger, Cramer, and Cho (2014) show that the re-employability of the long-term unemployed progressively declines over time, to the extent that they are more likely to exit the labor force than to become re-employed. The presence of more job openings does not lead to increased employment among individuals who are jobless for more than six months, and this pattern holds across all ages, industries and education levels (Ghayad & Dickens, 2012).

[7] Jung and Kuhn (2019) find that a shock at the top of the earnings distribution, such as the loss of a particularly good job, is a relevant source of persistent earnings losses.
(a) Age and time effects
(b) Time and cohort effects
(c) Age and cohort effects

Fig. 2. Age, time and cohort effects on conditional risky share.
This figure displays the estimated age, cohort and time effects on conditional risky share under different model specifications. Panel (a): the cohort effect is assumed to be constant across ages and periods; panel (b): the age effect is assumed to be constant across cohorts and periods; panel (c): the time effect is assumed to be the same across ages and cohorts. SCF data from 1992 to 2016 on households with heads aged between 21 and 70 years are used. Coefficients that are not statistically significant at the 5% level are set to zero.

initially reduces earnings by as much as 24%, and negative effects can last several years. Moreover, disorders reduce the probability of employment by about 14% (Currie & Madrian, 1999).

Whether personal disaster risk arises from layoffs or individual productivity declines, it is subject to incomplete insurance. Layoffs are usually partially insured by the US unemployment insurance system, but long-term unemployment is not. Personal productivity shocks are rarely insured by social welfare programs, except from major observable health problems, because of moral hazard. When awarded, disability benefits are more generous than unemployment benefits, offering a replacement rate of about 42% to the average worker (Gruber, 2000). The replacement rates are higher for low income people and for those who do not have employer-provided health insurance (Low & Pistaferri, 2015).

Of course, informal insurance mechanisms, including family support, may also exist. Guvenen and Smith (2014) infer the extent of overall partial insurance from a dynamic model of consumption and linear labor income shocks where agents learn about their income growth rates. The partial insurance parameter is estimated to be 0.45, implying that almost one-half of both permanent and transitory income shocks are smoothed away through mechanisms different from savings. Blundell, Pistaferri, and Preston (2008) also estimate the extent of partial insurance. While it varies across cohorts, their estimate on the whole sample is that about 36% of permanent shocks (and almost 95% of transitory shocks) are insured.

Last but not least, the extent of the coverage is *ex-ante* uncertain, adding to the uncertainty of the losses experienced in a personal disaster state. For instance, the structure of disability insurance has an initial claim stage and an appeal process, with fluctuations over time in the award rates. Importantly, such screening may be subject to error. According to Low and Pistaferri (2015), the probability of being rejected while having a severe work limitation exceeds 0.5. Against this varied background, our model allows for residual uninsured losses in the personal disaster state that, though small on average, are uncertain as to their actual size. Calibrations will focus on the case of an expected human capital erosion as low as 20% of the permanent labor income component.

In summary, the empirical evidence presented in this section serves two purposes. First, it shows that the relatively flat age profile of the (conditional) risky portfolio share is a strong feature of US households, confirmed also on our more recent cross-sectional data. We focus on this as the main stylized fact that a satisfactory model of life-cycle investment decisions should adequately match (see Section 5 below). Second, the available evidence on the main characteristics of human capital losses caused by long unemployment spells and disability, offers valuable insights on how to calibrate the size and the amount of uncertainty surrounding such earnings losses, that we exploit in the model's quantitative evaluation (Section 4).

3. A life-cycle model with personal disaster risk

Our model extends the life-cycle framework of Bagliano et al. (2019) to allow for a stochastic size of the loss in earnings prospects in case of a long unemployment spell. The labor income process is designed to yield a disastrous outcome for the unemployed worker only in rare circumstances.

The investor maximizes the expected discounted utility of consumption over working life, starting at age t_0, and retirement, which begins with certainty at age $t_0 + K$; she also wishes to leave a bequest. Life lasts at most T periods, and is governed by age-dependent life expectancy: at each date t, the survival probability of being alive at date $t + 1$ is p_t (with $p_{t_0-1} = 1$). Individual preferences are described by a time-separable power utility function:

$$\frac{C_{it_0}^{1-\gamma}}{1-\gamma} + E_{t_0}\left[\sum_{j=1}^{T} \beta^j \left(\prod_{k=-1}^{j-2} p_{t_0+k}\right)\left(p_{t_0+j-1}\frac{C_{it_0+j}^{1-\gamma}}{1-\gamma} + \left(1 - p_{t_0+j-1}\right) b \frac{\left(X_{it_0+j}/b\right)^{1-\gamma}}{1-\gamma}\right)\right] \tag{1}$$

where C_{it} is the level of consumption at time t, X_{it} is the amount of wealth the investor leaves as a bequest if death occurs, $b \geq 0$ is a parameter capturing the strength of the bequest motive, $\beta < 1$ is a utility discount factor, and γ is the constant relative risk aversion parameter.

3.1. Labor and retirement income

During working life individuals supply labor inelastically and receive exogenous stochastic earnings. We introduce personal disaster risk by modeling working life careers as a Markov chain with three possible states: employment (e), short-term unemployment (u_1) and a disaster state characterized by long-term unemployment (u_2). Individual labor market dynamics are driven by the following transition matrix:

$$\Pi_{s_t,s_{t+1}} = \begin{pmatrix} \pi_{ee} & \pi_{eu_1} & \pi_{eu_2} \\ \pi_{u_1e} & \pi_{u_1u_1} & \pi_{u_1u_2} \\ \pi_{u_2e} & \pi_{u_2u_1} & \pi_{u_2u_2} \end{pmatrix} = \begin{pmatrix} \pi_{ee} & 1-\pi_{ee} & 0 \\ \pi_{u_1e} & 0 & 1-\pi_{u_1e} \\ \pi_{u_2e} & 0 & 1-\pi_{u_2e} \end{pmatrix} \tag{2}$$

where $\pi_{nm} = \text{Prob}(s_{t+1} = m | s_t = n)$ with $n, m = e, u_1, u_2$ are the transition probabilities across states. A worker employed at t ($s_t = e$) can continue her employment spell at $t + 1$ ($s_{t+1} = e$) with probability π_{ee}, or can enter short-term unemployment ($s_{t+1} = u_1$) with probability $\pi_{eu_1} = 1 - \pi_{ee}$. If short-term unemployed at t ($s_t = u_1$), she exits unemployment ($s_{t+1} = e$) with probability π_{u_1e} or becomes long-term unemployed ($s_{t+1} = u_2$) with probability $\pi_{u_1u_2} = 1 - \pi_{u_1e}$. Finally, if the worker is long-term unemployed at t ($s_t = u_2$), she is re-employed in the following period ($s_{t+1} = e$) with probability π_{u_2e}, or remains in the disaster state with probability $\pi_{u_2u_2} = 1 - \pi_{u_2e}$.

Stochastic labor income is driven by permanent and transitory shocks. In each working period, labor income Y_{it} is generated by the following process:

$$Y_{it} = H_{it} N_{it} \qquad t_0 \leq t \leq t_0 + K \tag{3}$$

where N_{it} captures a stochastic transitory element, and $H_{it} = F(t, \mathbf{Z}_{it}) P_{it}$ represents the permanent income component. In particular, $F(t, \mathbf{Z}_{it}) \equiv F_{it}$ denotes a deterministic trend that depends on age (t) and a vector of individual characteristics ($\mathbf{Z}_{it}$) such as gender, marital status, household composition and education. The stochastic permanent component is modeled as a logarithmic random walk process: $P_{it} = P_{it-1} U_{it}$. We assume that $\omega_{it} = log(U_{it})$ and $\varepsilon_{it} = log(N_{it})$ are independent and identically normally distributed with variances σ_ω^2 and σ_ε^2 respectively.[8]

Labor income received by the employed individual at time t depends on her past working history since we allow unemployment and its duration to affect the permanent component of labor income. Thus, after one-period unemployment the permanent component H_{it} is equal to H_{it-1} eroded by a fraction Ψ_1, and after a two-period unemployment spell the permanent component, H_{it-1}, is eroded by a fraction Ψ_2, with $\Psi_2 > \Psi_1$. This introduces non-linearity into the expected permanent labor income, capturing the fact that the longer the unemployment spell, the larger is the worker's human capital depreciation (Guvenen et al., 2021; Schmieder et al., 2016). In compact form, the permanent component of labor income H_{it} evolves according to

$$H_{it} = \begin{cases} F(t, \mathbf{Z}_{it}) P_{it} & \text{if } s_t = e \text{ and } s_{t-1} = e \\ (1 - \Psi_1) H_{it-1} & \text{if } s_t = e \text{ and } s_{t-1} = u_1 \qquad t = t_0, \dots, t_0 + K \\ (1 - \Psi_2) H_{it-1} & \text{if } s_t = e \text{ and } s_{t-1} = u_2 \end{cases} \tag{4}$$

We model the human capital erosion parameters, Ψ_1 and Ψ_2, as random variables that follow standard *Beta* distributions with shape parameters (a_j, b_j): thus, $\Psi_j \sim Beta(a_j, b_j)$.[9] This distribution allows to represent outcomes, such as proportions, being defined on the interval (0,1), yielding the probability density of Ψ_j, with $j = 1, 2$, as:

$$f(\Psi_j : a_j, b_j) = \frac{\Psi_j^{a_j - 1}(1 - \Psi_j)^{b_j - 1}}{B(a_j, b_j)} \tag{5}$$

where $B(a_j, b_j)$ is a normalization constant to ensure that the total probability is 1. The expected value and the variance of Ψ_j, with $j = 1, 2$, are then equal to:

$$E(\Psi_j) = \frac{a_j}{a_j + b_j}, \ Var(\Psi_j) = \frac{a_j b_j}{(a_j + b_j)^2 (a_j + b_j + 1)}. \tag{6}$$

During unemployment, the worker receives unemployment benefits as a fixed proportion (ξ_1 and ξ_2 in the case of short-term and long-term unemployment, respectively) of her last working year labor income. Thus, the income received during unemployment spells is:

$$Y_{it} = \begin{cases} \xi_1 H_{it-1} & \text{if } s_t = u_1 \\ \xi_2 H_{it-2} & \text{if } s_t = u_2 \end{cases} \qquad t = t_0, \dots, t_0 + K \tag{7}$$

Finally, as in the standard life-cycle model, retirement income is certain and equal to a fraction λ of the permanent labor income earned in the last working year:

$$Y_{it} = \lambda F(t, \mathbf{Z}_{it_{0+l}}) P_{it_{0+l}} \tag{8}$$

where $t_0 + l$ is the last working period and λ is level of the replacement rate.

3.2. Investment opportunities

During both working life and retirement, savings can be invested in a short-term riskless asset, yielding a constant gross real return R^f, and one risky asset ("stocks") yielding stochastic gross real returns R_t^s in each period. The excess return of stocks is modeled as:

$$R_t^s - R^f = \mu^s + v_t^s \tag{9}$$

where μ^s is the expected stock premium and v_t^s is a normally distributed innovation, with mean zero and variance σ_s^2. We do not allow for excess return predictability and other forms of changing investment opportunities over time, as in Michaelides and Zhang (2017).

---

[8] We abstract from possible age-dependence in the persistence of earnings shocks as in Karahan and Ozkan (2013) and Sanchez and Wellschmied (2020). However, in Section D of the Supplementary Appendix, we allow for an age-dependent probability of entering long-term unemployment, thereby reducing the risk of personal disasters for younger workers.

[9] This modeling compactly represents the uncertainties surrounding possible future negative earnings shocks. These may include the award process of disability insurance or the differential personal impact of times of crisis, such as the Great Recession or the Covid pandemic, and of ordinary business cycle contractions.

At the beginning of each period, financial resources available to the individual for consumption and saving are given by the sum of accumulated financial wealth W_{it} and current labor income Y_{it}, which we call cash on hand $X_{it} = W_{it} + Y_{it}$. Given the chosen level of current consumption, C_{it}, next period cash on hand is given by

$$X_{it+1} = (X_{it} - C_{it})R_{it}^P + Y_{it+1} \tag{10}$$

where R_{it}^P is the investor's portfolio return:

$$R_{it}^P = \alpha_{it}^s R_t^s + \left(1 - \alpha_{it}^s\right) R^f \tag{11}$$

with α_{it}^s and $\left(1 - \alpha_{it}^s\right)$ denoting the shares of the investor's portfolio invested in stocks and in the riskless asset respectively. We do not allow for short sales and we assume that the investor is liquidity constrained. Consequently, the amounts invested in stocks and in the riskless asset are non-negative in all periods.

3.3. Solving the life-cycle problem

In this intertemporal optimization framework, the investor maximizes the expected discounted utility over her whole life span, by choosing the consumption and the portfolio rules given uncertain labor income and asset returns. Formally, the optimization problem is written as:

$$\max_{\{C_{it}\}_{t_0}^T,\{\alpha_{it}^s\}_{t_0}^T} \left(\frac{C_{it_0}^{1-\gamma}}{1-\gamma} + E_{t_0}\left[\sum_{j=1}^T \beta^j \left(\prod_{k=-1}^{j-2} p_{t_0+k}\right) \left(p_{t_0+j-1}\frac{C_{it_0+j}^{1-\gamma}}{1-\gamma} \right.\right.\right.$$
$$\left.\left.\left. + \left(1 - p_{t_0+j-1}\right) b\frac{\left(X_{it_0+j}/b\right)^{1-\gamma}}{1-\gamma}\right)\right]\right) \tag{12}$$

$$s.t. \quad X_{it+1} = (X_{it} - C_{it})\left(\alpha_{it}^s R_t^s + \left(1 - \alpha_{it}^s\right)R^f\right) + Y_{it+1} \tag{13}$$

with the labor income and retirement processes specified above and the no-short-sales and borrowing constraints imposed. Given its intertemporal nature, the problem can be restated in a recursive form, rewriting the value of the optimization problem at the beginning of period t as a function of the maximized current utility and of the value of the problem at $t+1$ (Bellman equation):

$$V_{it}\left(X_{it}, P_{it}, s_{it}\right) = \max_{C_{it}, \alpha_{it}^s} \left(\frac{C_{it}^{1-\gamma}}{1-\gamma} + \beta E_t\left[p_t V_{it+1}\left(X_{it+1,} P_{it+1}, s_{it+1}\right)\right.\right.$$
$$\left.\left. + \left(1 - p_t\right) b\frac{\left(X_{it+1}/b\right)^{1-\gamma}}{1-\gamma}\right]\right) \tag{14}$$

At each time t the value function V_{it} describes the maximized value of the problem as a function of three state variables: cash on hand at the beginning of time t (X_{it}), the stochastic permanent component of income at beginning of t (P_{it}), and the labor market state ($s_{it} = e, u_1, u_2$). The Bellman equation can be written by making the expectation over the employment state at $t+1$ explicit:

$$V_{it}\left(X_{it}, P_{it}, s_{it}\right) = \max_{C_{it}, \alpha_{it}^s} \left(\frac{C_{it}^{1-\gamma}}{1-\gamma}\right.$$
$$+ \beta \left[p_t \sum_{s_{it+1}=e,u_1,u_2} \pi\left(s_{it+1}|s_{it}\right) \widetilde{E_t V}_{it+1}\left(X_{it+1}, P_{it+1}, s_{it+1}\right)\right.$$
$$\left.\left. + \left(1 - p_t\right) b \sum_{s_{it+1}=e,u_1,u_2} \pi\left(s_{it+1}|s_{it}\right)\frac{\left(X_{it+1}/b\right)^{1-\gamma}}{1-\gamma}\right]\right) \tag{15}$$

where $\widetilde{E_t V}_{it+1}$ denotes the expectation operator taken with respect to the stochastic variables ω_{it+1}, ε_{it+1}, and v_{it+1}^s. The history dependence that we introduce in our set-up by making unemployment affect subsequent labor income prospects prevents having to rely on the standard normalization of the problem with respect to the level of P_t. To highlight how the evolution of the permanent component of labor income depends on previous individual labor market dynamics we write the value function at t in each possible state as (dropping the term involving the bequest motive):

$$V_{it}(X_{it}, P_{it}, e) = u(C_{it}) + \beta p_t \begin{cases} \begin{cases} V_{it+1}(X_{it+1}, P_{it+1}, e) & \text{with prob. } \pi_{e,e} \\ \text{with } P_{it+1} = P_{it}e^{\omega_{it+1}} & \text{and} \\ X_{it+1} = (X_{it} - C_{it})R_{it}^P + F_{it+1}P_{it+1}e^{\varepsilon_{it+1}} \end{cases} \\ \begin{cases} V_{it+1}(X_{it+1}, P_{it+1}, u_1) & \text{with prob. } 1 - \pi_{e,e} \\ \text{with } P_{it+1} = (1 - \Psi_1)P_{it} & \text{and} \\ X_{it+1} = (X_{it} - C_{it})R_{it}^P + \xi_1 F_{it}P_{it} \end{cases} \end{cases}$$

$$V_{it}(X_{it}, P_{it}, u_1) = u(C_{it}) + \beta p_t \begin{cases} \begin{cases} V_{it+1}(X_{it+1}, P_{it+1}, e) & \text{with prob. } \pi_{u_1,e} \\ \text{with } P_{it+1} = (1-\Psi_1)P_{it-1}\,e^{\omega_{it+1}} = P_{it}\,e^{\omega_{it+1}} & \text{and} \\ X_{it+1} = (X_{it} - C_{it})R^p_{it} + F_{it-1}P_{it+1}e^{\varepsilon_{it+1}} \end{cases} \\[1em] \begin{cases} V_{it+1}(X_{it+1}, P_{it+1}, u_2) & \text{with prob. } 1-\pi_{u_1,e} \\ \text{with } P_{it+1} = (1-\Psi_2)(1-\Psi_1)P_{it-1} = (1-\Psi_2)P_{it} & \text{and} \\ X_{it+1} = (X_{it} - C_{it})R^p_{it} + \xi_2 F_{it-2}P_{it-2} \end{cases} \end{cases}$$

$$V_{it}(X_{it}, P_{it}, u_2) = u(C_{it}) + \beta p_t \begin{cases} \begin{cases} V_{it+1}(X_{it+1}, P_{it+1}, e) & \text{with prob. } \pi_{u_2,e} \\ \text{with } P_{it+1} = P_{it}e^{\omega_{it+1}} & \text{and} \\ X_{it+1} = (X_{it} - C_{it})R^p_{it} + F_{it-2}P_{it+1}e^{\varepsilon_{it+1}} \end{cases} \\[1em] \begin{cases} V_{it+1}(X_{it+1}, P_{it+1}, u_2) & \text{with prob. } 1-\pi_{u_2,e} \\ \text{with } P_{it+1} = (1-\Psi_2)P_{it} \text{ and} \\ X_{it+1} = (X_{it} - C_{it})R^p_{it} + \xi_2 F_{it-2}P_{it-2} \end{cases} \end{cases} \tag{16}$$

This problem has no closed form solution, and we obtain the optimal values for consumption and portfolio shares by means of numerical techniques. To this aim, we apply a backward induction procedure starting from the last possible period of life T and computing optimal consumption and portfolio share policy rules for each possible value of the continuous state variables (X_{it} and P_{it}) by means of the standard grid search method.[10] Going backwards, for every period $t = T-1, T-2, \ldots, t_0$, we use the Bellman equation (15) to obtain optimal rules for consumption and portfolio shares.

4. Calibration

Calibration of the model requires choosing parameters of the investor's preferences, labor and retirement incomes, and the moments of stock returns. For reference, we initially solve the model by abstracting from the unemployment risk as in Cocco et al. (2005), a standard benchmark in the literature. Then, we introduce unemployment risk and consider two scenarios: (i) unemployment spells cause permanent deterministic income losses; and (ii) unemployment implies a disaster risk, since it has permanent but uncertain and possibly large consequences on the worker's earnings ability.

Across all scenarios, the agent begins her working life at the age of 20 and works for (a maximum of) 45 periods (K) before retiring at the age of 65. After retirement, she can live for a maximum of 35 periods until the age of 100. In each period, we take the conditional probability of being alive in the next period p_t from the life expectancy tables of the US National Center for Health Statistics. We set the utility discount factor $\beta = 0.96$, and the parameter capturing the strength of the bequest motive $b = 2.5$.[11] Finally, the benchmark value for the relative risk aversion is $\gamma = 5$. This value is relatively standard in the literature (Chang et al., 2018; Gomes et al., 2008; Gomes & Michaelides, 2005) and captures an intermediate degree of risk aversion. However, Cocco et al. (2005) choose a value as high as 10 in their benchmark setting. The riskless interest rate is set at 0.02, with an expected equity premium $\mu^s = 0.04$ with standard deviation $\sigma_s = 0.157$, as in Cocco et al. (2005). Finally, we impose a zero correlation between stock return innovations and permanent labor income disturbances. Table 2 summarizes the benchmark values of relevant parameters.

4.1. Labor income and unemployment risk

The labor income process is calibrated using the estimated parameters for US households with high school education (but not a college degree) in Cocco et al. (2005). For the high school group, the variances of the permanent and transitory shocks (ω_{it} and ε_{it} respectively) are equal to $\sigma^2_\omega = 0.0106$ and $\sigma^2_\varepsilon = 0.0738$. After retirement, income is a constant proportion λ of the final (permanent) labor income, with $\lambda = 0.68$. The parameter values assumed above are maintained across all scenarios. Section C of the Supplementary Appendix confirms our results for different education levels (no high school degree, and college degree).

We use data from the Current Population Survey (CPS) to calibrate the transition probabilities from employment to unemployment to reflect the risk of entering unemployment along with the observed average unemployment rates at different durations. According to the evidence based on CPS reported in Kroft et al. (2016), the annual transition probability from employment to unemployment is 4%. Given the duration dependence and the steady decline in the annual outflow rate from unemployment to employment during the first year of unemployment (Kroft et al., 2016), we set the probability of leaving unemployment after the first year at 85%. This calibration appears quite conservative, considering that the measured chance of being employed 15 months

---

[10] The problem is solved over a grid of values covering the space of both the state variables and the controls in order to ensure that the obtained solution is a global optimum.

[11] This parameter bears the interpretation of the number of years of her descendants' consumption that the investor intends to save for.

Table 2

Calibration parameters.

Description	Parameter	Value
Working life (max)	T	20–65
Retirement (max)	$t_0 + K$	65–100
Discount factor	β	0.96
Risk aversion	γ	5
Replacement ratio	λ	0.68
Variance of permanent shocks to labor income	σ_ω^2	0.0106
Variance of transitory shocks to labor income	σ_ϵ^2	0.0738
Riskless rate	r	0.02
Excess returns on stocks	μ^s	0.04
Variance of stock returns innovations	σ_s^2	0.025
	Unemployment no disaster	Unemployment with disaster risk
Unemployment benefits		
Short-term unemployed (ξ_1)	0.3	0.3
Long-term unemployed (ξ_2)	0.1	0.1
Human capital erosion		
Short-term unemployed (Ψ_1)	0	0
Long-term unemployed (Ψ_2)	0.20	(expected) 0.20
—*Beta* distribution a_2	–	0.01
—*Beta* distribution b_2	–	0.04

This table reports benchmark values of relevant parameters.

later for those who had been unemployed 27 weeks or more is only 36% (Krueger et al., 2014). Finally, we set the probability of persisting in a state of long-term unemployment at 15%, to be consistent with the average U.S. long-term unemployment rate. Thus, individual labor market dynamics are driven by the following transition matrix[12]:

$$\Pi_{s_t, s_{t+1}} = \begin{pmatrix} 0.96 & 0.04 & 0 \\ 0.85 & 0 & 0.15 \\ 0.85 & 0 & 0.15 \end{pmatrix} \tag{17}$$

Indeed, the assumed transition matrix (17) yields an unconditional probability of being short-run unemployed equal to 3.8% and a probability of being long-run unemployed as low as 0.7%, in line with the historical evidence on the short- and long-term unemployment rates in the U.S. This calibration represents a crucial difference from Bagliano et al. (2019), where transition probabilities were chosen to yield a much higher long-run unemployment rate (1.72%), observed in the U.S. only in the exceptional and short-lived period following the 2008–9 Great Recession.

The available empirical evidence on job displacement shows that job losses affect earnings far beyond the unemployment spell, though the range of the estimated effects varies considerably. For example, the estimates for immediate losses following displacement may range from 30% (Couch & Placzek, 2010) to 40% of earnings (Jacobson, LaLonde, & Sullivan, 1993b). Earnings losses are shown to be persistent in a range from 15% (Couch & Placzek, 2010) to about 25% (Jacobson et al., 1993a) of their pre-displacement levels. These estimates abstract from the effect of unemployment duration, while Cooper (2013) finds that earnings losses are larger the longer unemployment lasts. Also, based on administrative data, Jacobson, LaLonde, and Sullivan (2005) estimate that average earnings losses for displaced workers amount to 43%–66% of their pre-displacement wage.

This body of evidence, combined with a probability of finding a job after being unemployed for 24 months as low as 40% (Kroft et al., 2016), leads us to calibrate an expected drop in human capital, following a long-term unemployment spell, of about 20% leaving open the possibility of rare but much larger losses. Thus, while Ψ_1 is kept equal to 0 with certainty, Ψ_2 follows a *Beta* distribution with expected value of 20% and a standard deviation close to 40%. This calibration for the distribution Ψ_2 delivers a median value for the proportional human capital erosion close to 0% and a 75th percentile lower than 1.5%. Only a small fraction of the long-term unemployed suffers more sizable losses, even reaching 100% of the permanent income component.

Thus, the long-term consequences of not working for a long time are modest for the majority of workers but possibly very large in rare situations. In fact, in our benchmark calibration, if a worker is currently employed, she will enter long-run unemployment and suffer a earnings loss larger than 1.5% (therefore experiencing a "personal disaster") only with a 0.15% probability; even if the worker is already unemployed, the probability of being hit by a personal disaster is as small as 3.75%. This is consistent with several studies exploring the effects of unemployment on future labor income and separation rates: for example, Guvenen et al. (2017) find that income losses after long-term unemployment may be substantial and are highly heterogeneous, as recently confirmed by Gregory et al. (2021) and Guvenen et al. (2021).

Finally, unemployment benefits are calibrated according to the US unemployment insurance system. In particular, considering that the replacement rate with respect to last labor income is on average low and state benefits are paid for a maximum of 26

---

[12] In Section D of the Supplementary Appendix, we assess the robustness of our results to assuming age-dependent transition probabilities, whereby young workers are less likely to enter long-term unemployment than middle-aged workers.

weeks,[13] we set $\xi_1 = 0.3$ in case of short-term unemployment spells as in Branger et al. (2019), and $\xi_2 = 0.1$ for the long-term unemployed.[14]

For comparison, we consider a calibration of the model without unemployment risk. This "*no unemployment risk*" scenario corresponds to the standard life-cycle set up with $\pi_{ee} = 1$ and all other entries equal to zero in the transition probability matrix (17). In addition, to highlight the effects of permanent consequences of unemployment on future earnings prospects, we consider a third calibration by adding the unemployment risk embedded in matrix (17) with deterministic human capital erosion. In this "*unemployment without disaster risk*" scenario, long-term unemployment has deterministic permanent consequences on future earnings implying a human capital loss of 20% (i.e. $\Psi_1 = 0$ and $\Psi_2 = 0.20$), and closely matching (Bagliano et al., 2019), where the human capital loss is set at 25% for all long-term unemployed.

5. Results

In this section we present our main results on the optimal life-cycle portfolio allocation pattern in the presence of personal disaster risk and assess how close they match major observed empirical regularities. We start with a brief description of optimal investment policies.

5.1. Optimal policies

Fig. 3 compares investors' optimal stock shares in the case of *no unemployment* and in the case of unemployment with deterministic human capital erosion (i.e. *unemployment without disaster risk*), jointly displayed in panel (a), to optimal shares implied by our preferred scenario of unemployment with uncertain human capital erosion (i.e. *unemployment with disaster risk*), shown in panel (b). The figure plots the optimal stock share as a function of cash on hand at three different ages (20, 40, and 70).

In the cases of no unemployment and unemployment without disaster risk, we obtain standard life-cycle results. Labor income acts as an implicit risk-free asset and affects the optimal portfolio composition depending on an investor's age and wealth. For example, at age 20 the sizable implicit holding of the risk-free asset (through human capital) makes it optimal for less-wealthy investors to tilt their portfolio towards the risky financial asset. Indeed, for a wide range of wealth levels, agents optimally choose to be fully invested in stocks. The optimal stock holding decreases with financial wealth because of the relatively lower implicit investment in (risk-free) human capital.[15]

When the model is extended to allow for uncertain permanent effects of unemployment spells on labor income prospects (*unemployment with disaster risk*), with the parameters governing the proportional erosion of permanent labor income set at $\Psi_1 = 0$ after one year of unemployment and at an expected $\Psi_2 = 0.2$ after 2 years, the resulting policy functions are shifted abruptly leftward. The optimal stock share still declines with financial wealth but a 100% share of investment in stocks is optimal only at very low levels of wealth. In this case, long-term unemployment implies an uncertain loss of future labor income which severely reduces the level of human capital and increases its risk at any age. Thus, for almost all levels of financial wealth, stock investment is considerably lower than in the case of no disaster risk.

5.2. Life-cycle profiles

On the basis of the optimal policy functions, we simulate the whole life-cycle consumption and investment decisions of 100,000 agents. Fig. 4, panel (a), shows the average optimal equity portfolio shares plotted against age. In the case of no unemployment risk (dotted line), the well-known downward sloping pattern emerges. Over the life cycle the proportion of overall wealth implicitly invested in the riskless asset through human capital declines with age. Consequently, at early stages of the life cycle, optimal stock investment is about 100% and decreases with age to reach around 80% at retirement. When we consider unemployment risk with deterministic human capital erosion of 20% (dashed line), the optimal portfolio share of stocks still declines with age, though being only slightly lower at all ages, with a 100% optimal stock share only for very young investors.

However, when we account for disaster risk (solid line), the optimal stock investment is reduced at any age and almost flat, at around 45%–50%. The risk of potentially losing a substantial portion of future labor incomes reduces the level of human capital and increases its riskiness. Since this effect is more relevant for younger workers, it induces a lower optimal stock investment conditional on financial wealth especially when young (see Fig. 3, panel b). Consequently, the age profile remains flat over the whole working life. In the subsequent retirement years, the presence of an operative bequest motive determines the still relatively low level of risky

---

[13] No additional weeks of federal benefits are available in any state: the temporary Emergency Unemployment Compensation (EUC) program expired at the end of 2013, and no state currently qualifies to offer more weeks under the permanent Extended Benefits (EB) program.

[14] Our results go through also when we assume a more generous long-run unemployment replacement rate of 0.5. Meghir and Pistaferri (2004) acknowledge that layoffs are partially insured by the unemployment insurance system, while individual productivity shocks, other than major observable health shocks, are rarely insured in any formal way. As for other welfare programs, we do not model basic consumption needs and therefore do not consider basic consumption insurance.

[15] The optimal policies at age 70 coincide in the three scenarios, since retired workers do not face any form of unemployment risk. They are nevertheless shown in Fig. 3 for comparison with policies that are optimal during working life (at age 20 and 40).

(a) No unemployment risk - Unemployment without disaster risk

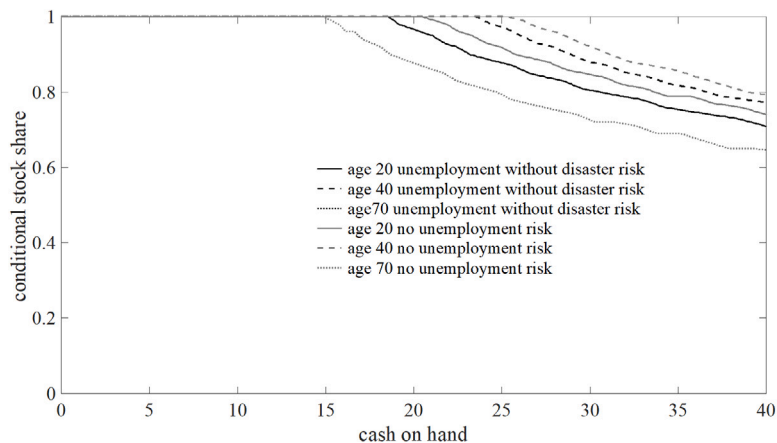

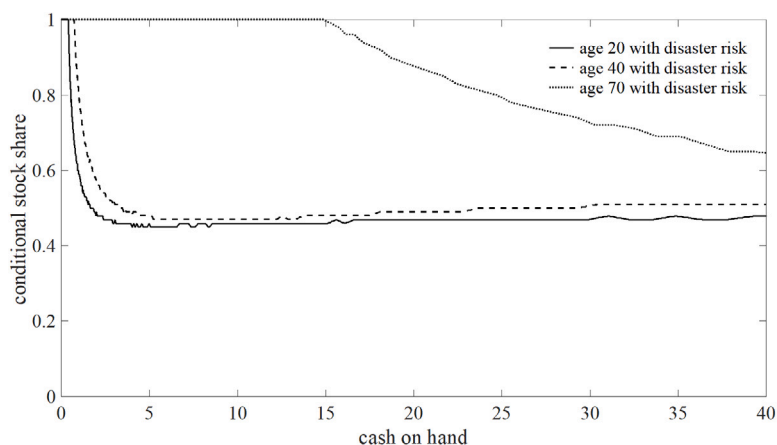

(b) Unemployment with disaster risk

Fig. 3. Policy functions.
This figure shows the portfolio rules for stocks as a function of cash on hand for an average level of the stochastic permanent labor income component. The policies refer to selected ages: 20, 40, and 70. The two panels refer to the cases of no unemployment and of unemployment without disaster risk (panel a), and of unemployment with disaster risk (panel b), respectively. In the case of unemployment without disaster risk, the human capital loss is 20% with certainty; in the case of unemployment with disaster risk, the expected human capital loss is 20%. Cash on hand is expressed in ten thousands of U.S. dollars.

investment.[16] Allowing for state-dependent labor market transition probabilities, as in Branger et al. (2019), would strengthen our results.[17]

These findings highlight that it is the remote possibility of incurring potentially large negative shocks to human capital, albeit small in expectation, that dampens the incentive to invest in stocks. They portray the effects on risk-taking of the "unusual" negative shocks that explain the consumption dynamics of US households in Arellano et al. (2017) across the earnings distribution. The reduction in the optimal portfolio share allocated to stocks is due to higher wealth accumulation, in turn induced by larger precautionary savings.

Panel (b) of Fig. 4 displays the average financial wealth accumulated over the life cycle for the three scenarios considered. In the face of possible, albeit rare, human capital depreciation, individuals accumulate substantially more financial wealth during their working life to buffer possible disastrous labor market outcomes. Optimal consumption when young consequently falls, but it is much higher during both late working years and retirement years.

---

[16] Importantly, our results are robust to the adjustment of the income diffusion volatility and drift rate to match the mean and variance of the income process in the standard calibration of Cocco et al. (2005). Details of this robustness analysis are available from the authors.

[17] In Branger et al. (2019), the main driver of the reduction in the optimal risk-taking by young workers is the decline in earnings due to unemployment (increasing in unemployment duration) and the state-dependence of unemployment and re-employment probabilities.
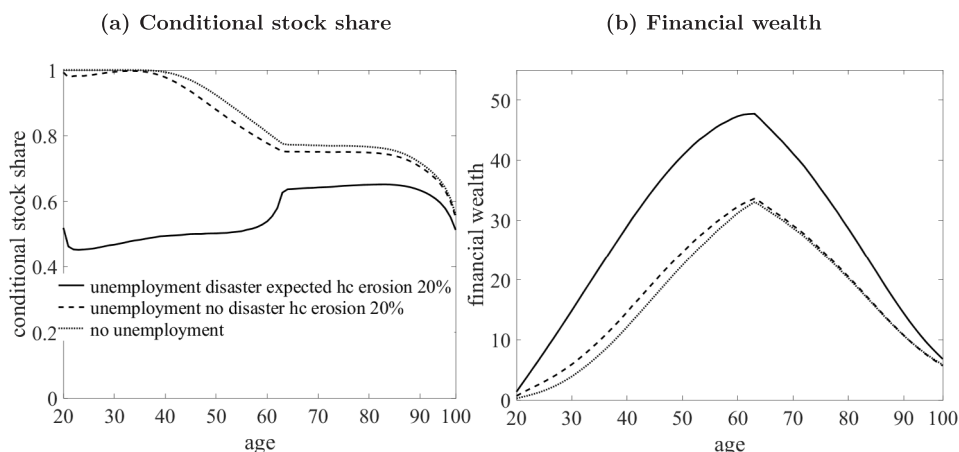

(a) Conditional stock share   (b) Financial wealth

Fig. 4. Life-cycle average profiles.
The figure displays the mean simulated stock investment, and financial wealth accumulation life-cycle profiles in panel (a) and (b), respectively. Age ranges from 20 to 100, with retirement occurring at the age of 65. The three lines correspond to no unemployment risk (dotted line); unemployment without disaster risk (dashed line); unemployment with disaster risk (solid line). In the case of unemployment without disaster risk, the human capital loss is 20% with certainty; in the case of unemployment with disaster risk, the expected human capital loss is 20%. Financial wealth is expressed in ten thousands of U.S. dollars.

Fig. 5. Life-cycle profiles of savings rate.
This figure displays the savings rate dynamics for individuals of age 20 to 100, relative to total income (i.e. labor income plus financial income). The two lines correspond to unemployment without disaster risk (dotted line) and unemployment with disaster risk (solid line). In the case of unemployment without disaster risk, the human capital loss is 20% with certainty. In the case of unemployment with disaster risk, the expected human capital loss is 20%.
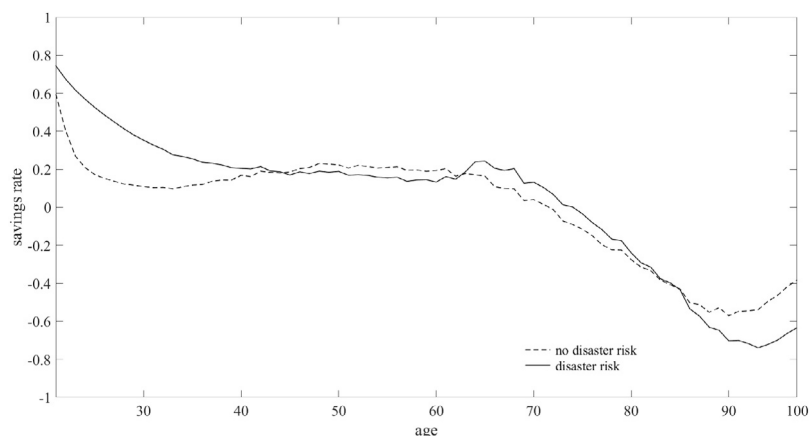

Fig. 5 displays the life-cycle profile of the ratio between savings and total (financial plus labor) income.[18] When the worker faces disaster risk, her average propensity to save is higher than in the case of unemployment without disaster risk throughout the first two decades of working life. Such propensity monotonically decreases in age, converging to the known pattern when the worker is in her mid-forties. The figure clearly shows the impact on savings of the resolution of uncertainty as individuals age.[19]

These results suggest that the prospect of a higher benefit, cushioning disastrous outcomes, could mitigate the adverse impact of long-term unemployment on human capital, reducing the need for cautious investing and saving during early working life. The variation of institutions across countries may thus generate different life-cycle patterns in equity investing. In this light, the decreasing stock holdings in Norwegian data detected by Fagereng et al. (2017), may be a consequence of higher long-term unemployment benefits with respect to the US.

Higher savings obviously implies lower consumption when young. What is less obvious is whether higher accumulated wealth shields consumption from the skewness of labor income shocks. Table 3 reports the mean and the standard deviation of the skewness

---

[18] In the case of no unemployment risk (not shown), the optimal savings age profile is very close to the case of unemployment with no disaster risk (dotted line).

[19] Data on Norwegian households show that they engage in additional saving, shifting portfolio composition towards safe assets, in the years prior to unemployment. There is depletion of savings after the job loss (Basten, Fagereng, & Telle, 2016).

Table 3
Skewness of labor income shocks and consumption growth rates.

	Labor income shocks	Consumption growth
Disaster risk	−2.817	−0.32
	(0.814)	(0.19)
No disaster risk	−0.007	0.03
	(0.026)	(0.27)

The table reports the mean and the standard deviation of the skewness of labor income shocks (permanent plus transitory) and consumption growth rates (between age t and age $t-1$) faced by 100,000 simulated investors.

of labor income shocks and of consumption growth rates across individuals during working life. Without disaster risk, the average skewness of labor income shocks is negligible (−0.007), while with disaster risk is sizably negative (−2.817), in line with values found in the literature on PSID data, ranging from 0 to −4 (De Nardi et al., 2020).

The labor income process that we consider is consistent with empirical earnings dynamics displaying substantial deviations from lognormality. For instance, Guvenen et al. (2021) find that negative shocks to earnings, while small on average, may be large in rare cases. In our model, large negative shocks are associated with the rare event that, after experiencing long-term unemployment, the worker cannot restore her previous earnings capacity.

Moreover, with disaster risk the average skewness of consumption growth rates is negative (−0.32), close to the estimate (−0.31) obtained by Bekaert and Engstrom (2017) on quarterly growth rates. Overall, we view our results as broadly consistent with the evidence of partial insurance against permanent income shocks (Arellano et al., 2017), and with models that attribute the negative skewness of consumption growth rates to permanent shock to labor income prospects (as in Bekaert & Engstrom, 2017) rather than to large transitory shocks (as in Gabaix, 2012).

However, our adopted income process does not fully reflect the non-linearities in income dynamics recently documented by the empirical literature. Hence, in Section A of the Supplementary Appendix we investigate whether our results are robust to different specifications of the (non-linear) labor income dynamics, along the lines of Arellano et al. (2017) and Guvenen et al. (2021).

5.2.1. Heterogeneity

The above results imply that the optimal stock investment is flat in age, even for a moderately risk averse worker. In the face of a rare but large human capital depreciation, workers on average invest about 50% of their financial wealth in stocks. However, this average pattern may hide considerable differences across agents. The present section investigates the distribution across agents of both conditional optimal stock share and accumulated wealth.

Panel (a) of Fig. 6 shows the 25th, 50th and 75th percentiles of the distributions in the case of unemployment without disaster risk.[20] Both the optimal stock share and the stock of accumulated financial wealth are highly heterogeneous across workers as well as retirees. The exception is young workers as they tilt their entire portfolio towards stocks given the relatively riskless nature of their human capital. Heterogeneity of portfolio shares depends on the shape and movements through age of the policy functions displayed in Fig. 3, relating optimal stock shares to the amount of available cash on hand, and on the level of cash on hand itself. Relatively steep policy functions imply that even small differences in the level of accumulated wealth result in remarkably different asset allocation choices. At the early stage of the life cycle, when accumulated financial wealth is modest, it is optimal for all workers to be fully invested in stocks. As investors grow older, different realizations of background risk induce large differences in savings and wealth accumulation. This situation pushes investors on the steeper portion of their policy functions and determines a gradual increase in the heterogeneity of optimal risky portfolio shares during their working life. After retirement, investors decumulate their financial wealth relatively slowly, due to the bequest motive, and still move along the steeper portion of their relevant policy functions; as a consequence, the dispersion of optimal shares tends to persist.

Panel (b) of Fig. 6 displays the life-cycle distribution of stock shares and financial wealth when workers face the prospect of unemployment with disaster risk. Compared with the previous case, optimal stock shares are much less heterogeneous. Heterogeneity shrinks during working life even for young workers, given the high human capital risk they bear at the beginning of their careers. Indeed, policy functions are relatively flat when long-term unemployment is uninsured (as shown in panel (b) of Fig. 3) implying that even large differences in the level of accumulated wealth result in homogeneous asset allocation choices.
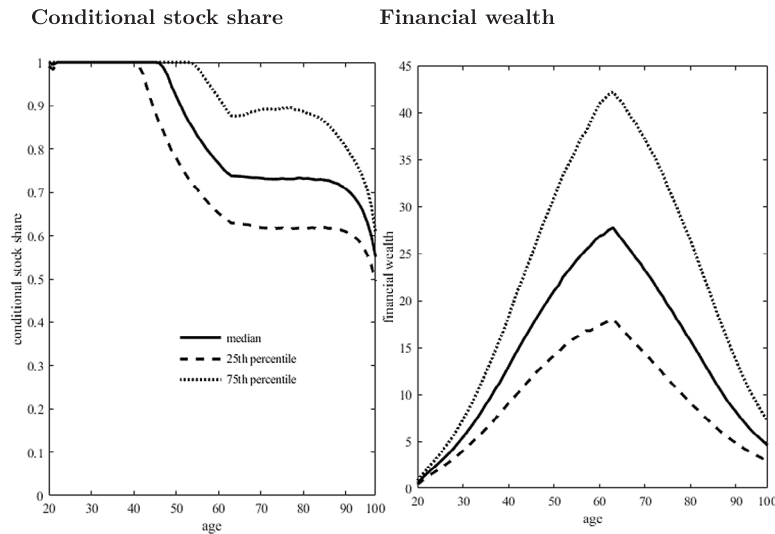

5.3. Uncertainty on the size of human capital loss

We now check the sensitivity of optimal life-cycle profiles to the amount of uncertainty surrounding the size of the human capital erosion caused by long-term unemployment. This is governed by the two shape parameters of the Beta distribution (a_2 and b_2), that we vary to allow for different degrees of uncertainty around an unchanged expected loss equal to 20% of the permanent income component.

Fig. 7 compares the benchmark case, in which human capital erosion has a standard deviation of 39%, with an alternative in which the standard deviation is reduced to 33%. Panel (b) of the figure displays the (inverse) cumulative distribution function of

---

[20] With no unemployment risk, all distributions are very close to the case of unemployment with no disaster.

(a) Unemployment without disaster risk

Conditional stock share   Financial wealth

(b) Unemployment with disaster risk

Conditional stock share   Financial wealth

Fig. 6. Life-cycle percentile profiles.
This figure displays the distribution of simulated equity share investment and financial wealth accumulation for individuals of age 20 to 100 in the case of unemployment without disaster risk, panel (a), and unemployment with disaster risk, panel (b). In the case of unemployment without disaster risk, the human capital loss is 20% with certainty. In the case of unemployment with disaster risk, the expected human capital loss is 20%. Financial wealth is expressed in ten thousands of U.S. dollars.

the human capital loss in the two cases. Compared with the benchmark, a reduction in the dispersion of the loss size implies that a lower fraction of the long-term unemployed may suffer an extremely large drop in earnings potential, making the occurrence of a disastrous outcome less likely. The associated life-cycle profile of the stock share, shown in panel (b), confirms the results of the benchmark case. Although the average stock share is slightly higher, being in the 50%–55% range over the working life, the age profile is remarkably flat, as in the benchmark case. This outcome supports the conclusion that rare but potentially disastrous labor income shocks may be relevant to understand cautiousness by young investors and their limited risk-taking in the stock market.[21]

---

[21] As shown in section F of the Supplementary Appendix, our results are confirmed also when we consider a transitory human capital loss, assuming that the earnings loss due to long-term unemployment is partially recovered when the worker finds a new job opportunity.

(a) Conditional stock share   (b) Human capital loss
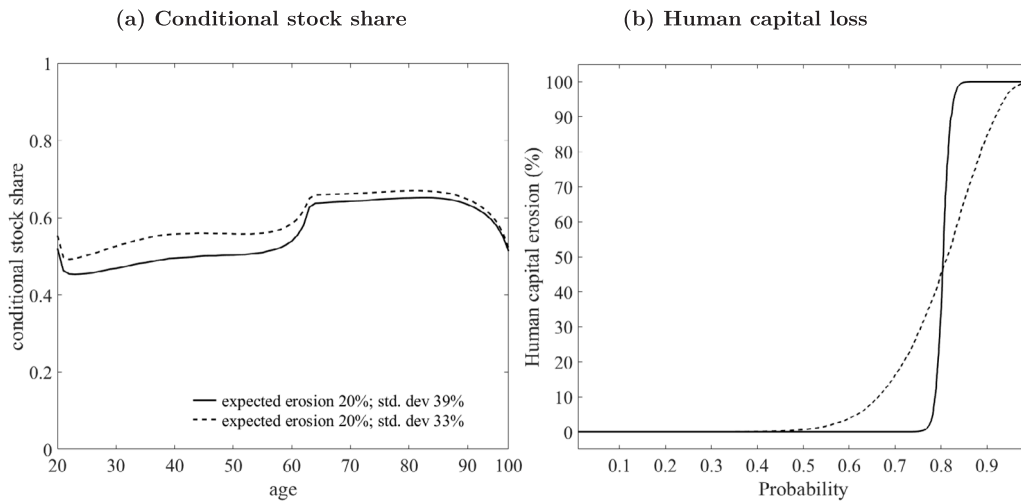

Fig. 7. Uncertainty on the size of human capital loss.
Panel (a) displays the life-cycle profile of optimal conditional stock holdings for two different parameterizations of the distribution of human capital erosion. Expected erosion is 20% in both cases, whereas the standard deviation is 39% in the benchmark case (solid line), and 33% in the alternative (dashed line). Panel (b) shows the two corresponding inverse cumulative distribution functions of the human capital erosion.
Fig. 8. Life-cycle conditional stock share profiles.
This figure displays the life-cycle profiles of conditional stock holdings of investors from age 20 to 70 observed in SCF data with that obtained from the benchmark model with disaster risk.

5.4. Matching empirical regularities

The key implication of our model is that optimal investment profiles are almost flat over the life cycle. In this section, we finally compare our results with conditional stockholdings for U.S. male investors observed in the Survey of Consumer Finances data (waves from 1992 to 2016).

Fig. 8 compares the stock portfolio shares of stock market participants for different age classes obtained from our model with the corresponding US SCF data. The matching is close during working years, which are the focus of this paper since we are concerned with personal disasters related to long-term unemployment. In fact, the model yields an average stock share over the working life of 49%, compared with the observed average share of 45.6%. Health disasters past retirement age, unrelated to unemployment spells, might improve the matching in the decumulation phase.

A related important result of the model with personal disaster risk, is that agents are induced to increase wealth accumulation over working years to cushion the prospect of a sizable human capital loss. Under this respect, the matching between the model and the data is less satisfactory.

Table 4
Wealth to income ratios.

(a) all ages			(b) age 65		
Discount factor β	Model	SCF data	Discount factor β	Model	SCF data
0.96	7.5		0.96	10.7	
0.85	4.3	4.8	0.85	6.5	6.7

The table shows the wealth-to-income ratios obtained from the simulated model and derived from the 1992–2016 waves of the US Survey of Consumer Finances, both at all ages and at the retirement age of 65. Model simulated ratios are obtained with two different values of the utility discount factor β: 0.96, as in the benchmark calibration, and 0.85.

In fact, the baseline calibration of our model delivers high average wealth-to-income ratios: 7.5 across the whole population (i.e. at all ages), with a peak of 10.7 at the retirement age of 65. Instead, the US Survey of Consumer Finances yields wealth-to-income ratios in the 5–7 range. This result is mainly attributable to our choice of the utility discount factor (β), that we calibrated at 0.96, a standard value in the literature (see e.g. Cocco et al., 2005; Fagereng et al., 2017).

Thus, we identified a value of the discount factor that is able to match more closely the observed wealth-to-income ratios. When $\beta = 0.85$, our model with personal disaster risk delivers average wealth-to-income ratios of 4.3 across all ages and of 6.5 at retirement age, much closer to the evidence, as shown in Table 4. This lower value of the discount factor is in line with recent findings: e.g. Fagereng et al. (2017) match the observed wealth-to-income ratio in Norwegian data with a discount factor lower than 0.80. As shown in detail in Section B of the Supplementary Appendix, our main result of a flat age profile of the risky investment share is fully confirmed also with a lower utility discount factor.[22]

6. Conclusions

This paper shows that even a small probability of experiencing human capital erosion of an uncertain, but potentially extreme, size generates optimal conditional stock shares in line with those observed in US data, along with a skewed consumption growth distribution. Non-linear income shocks, which have recently become essential in consumption studies, appear to play a first-order role in choices on risk-taking. Because of the remote possibility of a future personal disaster, younger workers face higher uncertainty concerning future income than older workers and optimally invest a higher portfolio share in the risk-free asset. These results are based on a methodological innovation in the way we model human capital erosion conditional on the occurrence of a rare disaster.

Our analysis has implications for the design of pension plans in the United States, that increasingly offer Target Date Funds (TDF) to plan members. While there is considerable dispersion in TDF returns, a common feature of their design tilts the composition of optimal portfolios towards equity investments when young (Balduzzi & Reuter, 2019). On the contrary, our results point out that a flatter design should fit workers with different career histories in the face of limited and uncertain protection against a future personal disaster. More generally, the pattern of risk-taking at different ages in TDF should be related to the share of uninsured disability and long-term unemployment risk.

The model also suggests that the observed variation in the age pattern of stock investing across countries may depend on the insurance coverage against personal disasters. Moreover, it points to the possibility that compound lotteries, such as the disasters modeled in this paper, potentially play a role in explaining both the low consumption levels of the elderly and the equilibrium risk premium. We leave the systematic investigation of these insights for future research.
